## Introduction

Markov Decision Processes (MDPs) provide a good, robust formal framework for modeling a large variety of stochastic planning and decision problems, but they are unsuitable to realistic problems, in particular, to solve problems in rapidly changing environments. The existing approaches use Markov decision processes to produce a policy of execution for a static set of tasks; in a changing environment (i.e. with an evolving set of tasks), a complete computation of the optimal policy is necessary. We consider a queue of tasks that can change on-line. Potential application of this approach would be an adaptive retrieval information engine (Arnt *et al.* 2004). Our main claim is that it is possible to dynamically compute good decisions without completely calculating the optimal policy. Similar approaches have been developed to deal with MDPs with large state spaces using different decomposition techniques (Boutilier, Brafman, & Geib 1997; Parr 2000). A similar dynamic resource allocation problem has been developed in (Meuleau *et al.* 1998). A non dynamic approach has been developed for robots in (Schwarzfischer 2003).

It has been shown in (Mouaddib & Zilberstein 1998) that it is possible to find an optimal policy for this kind of problem. This optimal solution suffers from a lack of flexibility to cope with changes in a dynamic environment. We develop an approach which provides more flexibility for MDPs to deal with dynamic environments. This approach consists of two steps. The first step consists of an off-line pre-processing of tasks and the compilation of policies for all possible available resources. The second step is a quick on-line approximation of the policy of executing the current task given the current state of the queue.

## Problem Statement

### Description

We consider an autonomous agent which has the capability of performing different kinds of stochastic tasks  $T_1, T_2, \dots, T_t$  progressively. A **progressive task**  $T$  is executed stage by stage, and it can be stopped after any stage. A quality is associated with each stage of task  $T$ . The duration  $\Delta r$  of execution of each stage is uncertain. The utility of

a task is the sum of the quality of the executed stages. This formalism is described (Mouaddib & Zilberstein 1998) in details. For each type of task  $T_n$  we compute a **task performance profile**  $f_n(r)$  that corresponds to its local expected value (see Figure 4). It represents what the agent should expect to gain if a certain task is being accomplished with a quantity  $r$  of resources.

Given an ordered list composed by several instances of these progressive tasks (for example  $L = \{T_3, T_1, T_3, T_1, T_1, T_2, T_1, T_3, T_2, T_3, T_2\}$ ), the agent must perform some of them before a fixed deadline  $D$  to maximize the global utility. The queue of tasks evolves **dynamically**, during on-line phase. Tasks can appear or disappear everywhere (see Figure 1). Our goal then is to

Figure 1: Dynamic changes in the task list

find an effective way to decide quickly if it is desirable to continue with the current task or to change to another one. This local decision depends on the prediction of the **expected value** of the remaining tasks in the list.

**The decision problem** We are facing to a resource allocation problem: we consider time as a **resource**  $r$ , which is **limited** by  $D$ . The duration of execution of each task is **uncertain**, resource consumption is **uncertain**. The agent has to allocate some resources for the current task, and some for the remaining tasks. Differently speaking it must **decide** if it is preferable to continue its work on the current task, or to give it up and switch to another task, by taking into account the state of current task, the list of remaining tasks, and the available resources. Then, our resources allocation problem becomes a decision problem.

We present the formalism we use to solve our problem in a non-dynamic environment in the next paragraph, and in the next section we will explain how to cope with changes in the task list.

### An MDP controller

At each step, the agent has to make a decision about continuing the improvement (**Improve**) of the current task or

abandoning it in favor of the next task (**Move**). This decision depends on the current state of the decision process. In other words, it depends on the current state and the available resources. Consequently, the decision process respects the Markov property. We could deploy an *MDP* for the whole list of tasks, but we do not. The basic idea is to compute the policy of executing the current task. This policy  $\Pi_{T,L}$  depends on  $L$ , the list of remaining tasks, and  $T$  the current task. As long as  $L$  remains unchanged, the agent follows  $\Pi_{T,L}$ . If  $L$  changes, it updates the current policy of the current task to  $\Pi_{T,L_{new}}$ . When the agent moves to a new task  $T_{new}$ , it assesses the current list of remaining tasks  $L_{new}$  and then it derives a new policy  $\Pi_{T_{new},L_{new}}$ .

**Formal Framework** An MDP is a tuple  $\{S, \mathcal{A}, T, Rew\}$  where  $S$  is a set of states representing the amount of remaining resources  $r$ . Initially,  $s_0 = [D]$  where  $D$  is the deadline. Terminal states represent all the situations where  $r$  has been fully elapsed  $s = [r < 0]$ .  $\mathcal{A}$  is a set of actions  $\{\text{Move}, \text{Improve}\}$  (see Figure 3). The **Move** action is deterministic: the agent moves from the current task and examines the next one in the dynamic list. The second action is stochastic, **Improve** consists in spending a certain quantity of resources  $\Delta r$  in the next stage.  $T$  is a set of transitions,  $Rew$  is a reward function. In the following, we define what  $\{S, \mathcal{A}, T, Rew\}$  means in our context. The states represent resources remaining, the actions are **Improve** and **Move**, and the reward is the accumulated quality for all improvements previously achieved in the task. The transitions are given in the description of each progressive task type.

$$\Pr(s' = [r - \Delta r] | s = [r], \mathbf{I}) = P_{Stage}(\Delta r) \quad (1)$$

$$\Pr(s' = [r < 0] | s = [r], \mathbf{I}) = \sum_{\Delta r > r} P_{Stage}(\Delta r) \quad (2)$$

**Policy** When the agent starts to execute a task  $T$ , it computes a local policy  $\Pi_{T,L}$  where  $L$  represents the list of remaining tasks. Since the list  $L$  remains unchanged, it follows its policy  $\Pi_{T,L}$  (see Figure 2). As soon as  $L$  changes to  $L_{new}$ , the agent has to change the local policy  $\Pi_{T,L}$  to  $\Pi'_{T,L_{new}}$ . To do so, the computation of  $\Pi_{T,L_{new}}$  is based

Figure 2: A local policy

on a quick computation of the new expected values of actions **M** and **I**. We describe below how those functions are computed.

**Value function** In order to compute the policy, we use a value function  $V(s)$  based on the Bellman equation:

$$\begin{cases} V(s = [r \geq 0]) = Rew(s) + \max_{\mathbf{A}} \sum_{s'} \Pr(s'|s, \mathbf{A}) \cdot V(s') \\ V(s = [r < 0]) = 0. \end{cases}$$

Policy  $\Pi_{T,L}$  is local, therefore we estimate the value of the states after a **Move** action with a second value function that

we denote as  $EV$ .  $EV_L$  is the value the agent can expect to gain if it accomplishes tasks in  $L$  with  $r$  resources.  $V_{T,L}$  is the expected value of achieving task  $T$  taking into account tasks in  $L$ . In our context, the Bellman equation becomes:  $V_{T,L}(s = [r]) = Rew(s) +$

$$\max_{\mathbf{A}} \begin{cases} EV_L(s = [r]) & \text{if } \mathbf{A} = \mathbf{M} \\ \sum_{s'=[r \geq 0]} \Pr(s'|s, \mathbf{I}) \cdot (V_{T,L}(s')) & \text{if } \mathbf{A} = \mathbf{I} \end{cases} \quad (4)$$

where  $s' = [r - \Delta r]$  represents a possible state after the improvement. Equation 4 needs to be solved as soon as the queue  $L$  changes to  $L_{new}$ . This leads to a computation of  $EV_{L_{new}}$  and  $V_{T,L_{new}}$ . We compute first  $EV_{L_{new}}$ . Then, we obtain the new local policy  $\Pi'_{T,L_{new}}$  by computing the  $V_{T,L_{new}}$  function using a backward-chaining algorithm on all the states in  $T$ . Figure 3 represents the mechanism of action selection. In the current state the agent has 176 resources left. The dotted rectangles represent the remaining tasks in the queue  $L$ . Now, the problem is to compute the

Figure 3: Action selection

Expected Value  $EV_L$ . It is possible to compute the exact  $EV_L$  of an optimal policy  $\Pi_{T,L}^*$ . We just have to use the Bellman equation on all the possible future states in  $L$  with a backward chaining algorithm. But with this method, the generated *MDP* is very large. But if we add a task in the middle of this linear graph, we must re-deploy the Bellman equation. This solution is not convenient if tasks are often inserted in the list i.e. if the environment changes. We can still keep the *MDP* model for the local task, but we must find another way to compute  $EV_L$ . We must evaluate the Expected Value for the rest of the plan quickly. Therefore we have to sacrifice optimality.

Rather than computing  $EV_L$  using a global *MDP*, we divide this process into two phases. An off-line phase, where we compile performances profiles for each type of task (see Figure 4), and an on-line phase, where we recompute dynamically the  $EV_L$  function (see Figure 5) when it is necessary.

In fact, we are faced with an *MDP* decomposition problem. We create a local *MDP* for each type of tasks, and we compute policies for local *MDPs*  $\Pi_{T,\emptyset}$  (policy of executing  $T$  assuming  $L = \emptyset$ ). The local policies are represented by performance profiles. We recombine them on-line to obtain an approximate  $EV_L \simeq recomposition_{T' \in L}(V_{\Pi_{T',L}})$ .

(3) **Task performance profile construction** The first phase consists of the computation and the storage of the performance profile function for each task type. The performance profile function  $f_n(r)$  corresponds to the exact expected value if we have  $r$  resources to spent in the task of type

$T_n$ . We consider that this task is independent from the others, and we compute a policy for a local  $MDP$ , without the **Move** action. This means that we assume  $L = \emptyset$ . Differently speaking,  $f_n(r) = V_{\Pi_{T_n}, \emptyset}([r])$ . This computation is quick. The local  $MDP$  has few states, and each state is evaluated once. It only depends on the number of stages in the task, and also on the maximum amount of resources that the agent can spend in the tasks. Now, we have to combine all these functions  $f_n$  to find an  $EV_L$  function for a list composed of tasks of type  $\{T_1, T_2, \dots, T_n\}$ . This function must be a good approximation of the exact  $EV_L$ .

### Dynamic operation

#### Principle

This section is divided into two phases: the off-line phase, where we compute the performance profile  $f_n(r) = V_{\Pi_{T_n}, L}([r])$  for each task, and the on-line phase, where the agent recomposes the expected value function  $EV_L$ .

**Off-line: The task pre-processing** The performance profile functions  $f_n(r)$  of each task are increasing functions in  $r$ . Note that the more time the agent spends on a task, the higher the expected reward will be. These curves are also bounded by a maximum, which corresponds to the reward if the task is completely achieved. The curves give us several information. On the one hand we know the expected value for this task, while on the other, we know the quality cost ratio, i.e.  $f_n(r)/r$ . The first phase of the pre-processing consists of finding the best quality cost ratio among all tasks.

$$\max_{n,r} f_n(r)/r \quad (5)$$

Then we isolate the part of the curve which precedes this point, as figure 4 shows. We start again to seek the second best quality cost ratio, until all the curves are processed. We finally store the points and slices of curves  $c_{i,j}$  in a table  $R_T$  (cf algorithm 1).  $c_{i,j}$  is the  $j^{th}$  slice of curve  $f_i$ .

Figure 4: Finding the best ratio quality/cost

**On-line: Expected Value function reconstitution** It is the second phase. All the next computations are done at run time. We recompose the  $EV_L$  function with all the information that we stored during the off-line phase  $\{f_1, \dots, f_t\}$ ,  $R_T$ , and with the list. The method is simple (see Algorithm 2). We have a list of tasks  $= \{T_3, T_1, T_3, T_1, T_1, T_2, T_1, T_3, T_2, T_3, T_2\}$ , and we recompute the expected value for all possible values of  $r$ , which represents the remaining time at a given moment. Algorithm 2 is illustrated in figure 5. Basically, we want that

---

#### Algorithm 1 Task pre-processing

---

**Require:**  $\{f_1; \dots; f_t\}, R_T = \emptyset$   
1: **while**  $\forall i \leq t, \exists r, f_{T_i}(r) > 0$  **do**  
2:    $r'_i, f_{i'} = \max_{i,r} f_i(r)/r$   
3:    $R_T \leftarrow R_T \cup \{[r'_i, f_{i'}(r \leq r'_i)]\}$   
4:    $f_{i'}(r) = f_{i'}(r - r'_i) - f_{i'}(r'_i)$   
5: **end while**  
**Ensure:**  $R_T$

---

the agent maximizes its future rewards, i.e. its  $EV_L$ . Thus, the  $EV_L$  curve is recomposed incrementally by adding each slice of curve in  $R_T$  until all available resources has been fully elapsed. This problem is similar to the knapsack problem. We start to add the slice of curve that maximize the ratio quality/cost. We add as many slices as the number of tasks of that type in  $L$  allowed by the remaining resources. Then, we add the slice of curve that corresponds to the second ratio quality/cost in  $R_T$ . This processing continues until all slices of curve  $c_{i,j}$  in  $R_T$  have been added or the resources have been fully elapsed. In the example  $L$  con-

---

#### Algorithm 2 Reconstitution of the Expected Value function (approximation) $EV_L$

---

**Require:**  $R_T, L$   
1:  $threshold = 0$   
2:  $r = 0$   
3: **while**  $R_T \neq \emptyset$  **do**  
4:    $(r', f_{i'}) \leftarrow first(R_T)$   
5:   remove  $first(R_T)$  from  $R_T$   
6:    $n = \text{number of task } T_i \in L$   
7:   **for**  $i = r, i \leq n \times r', i^{++}$  **do**  
8:      $m = i \bmod r'$   
9:      $q = i \div r'$   
10:      $EV_L(i) = m \times f_{i'}(r') + f_{i'}(q) + threshold$   
11:   **end for**  
12:    $r = r + n \times r'$   
13:    $threshold = EV_L(r)$   
14: **end while**  
**Ensure:**  $EV_L$

---

tains four instances of the task  $T_1$ . In the previous section, i.e during the off-line phase, we found that the first part of the task of type  $T_1$  gives a maximum quality cost ratio for  $r_1$  resource. Consequently, if we have only  $r_1$  resources left, it will be better to spend them on a task  $T_1$ . Thus, we start by adding one time the corresponding slice of the curve  $f_1(0 \leq r \leq r_1)$ . We are not sure that the exact  $EV_L$  corresponds to the slice of curve we add, it is just an approximation. But we are sure that we can not expect<sup>1</sup> less than this slice of curve, i.e. the approximation we make is a lower bound for the exact expected value function. If it has  $r$  resources  $r_1 \leq r \leq 2 \times r_1$ , it can do the first part of a task  $T_1$ , and starts the second task  $T_1$ . Therefore, we add the same slice of curve on the top of the first one (see Figure 5). In our example, we have four tasks of type  $T_1$  in the list, so if we

<sup>1</sup>Note that it is an expectation. During the execution of this task we can have less reward than what we expected.

have more than  $r > 4 \times r_1$  resources, the agent can expect to start four times  $T_1$ . With the rest ( $r - 4 \times r_1$ ) it can expect to start another task. In  $R_T$ ,  $T_2$  is the best task to start after  $T_1$ . We add the corresponding slice of curve to  $EV_L$  between  $4 \times r_1$  and  $4 \times r_1 + r_2$ . We continue adding slices of curve while  $R_T$  is not empty. If the agent has more than  $R_{max}$  resources then it is certain to achieve all the tasks, with all their improvements. The approximation of  $EV_L$  is finished.

Figure 5: Reconstitution of  $EV_L(r)$

### How do we use this function in practice

**The dynamic on-line approximation** In the preceding section, we explained how to reconstitute the expected value. However in practice we do not need to know all the values of  $EV_L(r)$ . Let  $D - r_{now}$  be the resources remaining to complete the mission. Moreover, we can use only a maximum amount of resources  $r_{max}$  for the current task. In fact, we just compute  $EV_L$  for all  $r$  in  $[D - r_{now} - r_{max}, D - r_{now}]$ . We made this reconstitution in order to compare  $EV_L(r)$  obtained by our approach with that obtained while solving the whole MDP for all the remaining tasks in the list. The complexity of computation is proportional to the number of elements in  $R_T$ . Thus, the computation of  $EV_L(r)$  is quick and is more suitable to the dynamicity.

### Analysis

In this section, we make a comparison between  $EV_{exact}$ ,  $EV_{dyna}$ , and  $EV_{pw-linear}$ . This comparison concerns the time needed to compute each of them and the error made by our approach.

**Complexity Comparison** To compute  $EV_{exact}$  we develop a set of states  $\mathcal{S} = \{s = [r, imp, T]\}$ ,  $r$  are the remaining resources,  $imp$  the quality of the last improvement made, and  $T$  is the task in the queue.  $r$  is considered discreet. We use a backward chaining algorithm using the Bellman equation, therefore each state is evaluated only once. The complexity of  $EV_{exact}$  is linear in the number of states  $\#\mathcal{S}$ . But the state space is huge.  $m(EV_{exact}) = \#\mathcal{S} = R_{max} \times \prod_{T_i \in L} \#imp_{T_i}$ .  $m$  is a mesure of complexity.

$m(EV_{dyna}) = \sum_{R_T} \#c_{i,j} \times \#T_i$  where  $c_{i,j}$  is a slice of the

$T_i$  performance profile curve, and  $\#T_i$  the number of times where  $T_i$  appears in  $L$ .  $m(EV_{dyna})$  is linear in the size of  $R_T$  and  $L$ . There are much fewer slices in  $R_T$  than there are states in  $\mathcal{S}$ . Thus,  $m(EV_{dyna}) \leq m(EV_{exact})$ . For a queue of 100 tasks,  $EV_{exact}$  takes several minutes, and  $EV_{dyna}$

takes less than one second. More results can be found on <http://users.info.unicaen.fr/~slegloan/thesis/>.

**Value Comparison** Our approximation  $EV_{dyna}$  is just a lower bound of the  $EV_{exact}$  function. If all the tasks executions where deterministic,  $EV_{dyna}$  and  $EV_{exact}$  would be equal on some specific points, at the "end" of each slice (fig 6).

$$\forall r, EV_{dyna}(r) \leq EV_{exact}(r). \quad (6)$$

Unfortunately, our approximation is just a lower bound

Figure 6: Deterministic Tasks

Figure 7: With Uncertainty

of what the agent should expect to gain in the worst case. We intend to mesure the difference between  $EV_{dyna}$  and  $EV_{exact}$  in the future, in order to fill the gap between the two curves.

### Conclusion and future works

We have presented a robust solution that copes with uncertainty due to dynamicity of environment in stochastic planning problems. The Markovian approach allows us to cope with uncertainty. The progressive approach allows us to adapt the decision in a dynamic environment. Our work combines two approaches: Progressive tasks and decomposition of large MDPs. For the future, we intend to add multiple limited resources, like energy. We would also like to extend this approach to include more specific spatial and temporal constraints. This model can be adapted to a large set of problems in a dynamic and uncertain environment like robotic applications, and information retrieval agent.
